Module 02: Variables and Conditional Statements

Topics:

• More on Variables
• Conditional Statements
• Recursion in Python

Readings: ThinkP 5,6
Python allows us to change the values of variables

The following Python assignments are valid:

\[
\begin{align*}
    x &= "a" \\
    x &= 100 \\
    x &= 2\times x - 1
\end{align*}
\]
Can changing one variable affect another variable?

Consider running this program:

```python
x = 1000
y = x
x = "a"
```

What are the values of \( x \) and \( y \) now?
What does this mean for our programs?

• Values of variables may change throughout a program
• Order of execution is very important
• We can write programs that keep track of changing information, for example:
  – current location in a GPS program
  – player information in games
• We may not need a new variable for each intermediate calculation in a function
Local vs Global variables

• Variables defined inside a function are called *local* variables
  – Local variables only can be updated inside the function they are defined in

• Variables defined outside a function are called *global* variables
  – Global variables *cannot* be updated inside any functions in CS116.
Global constants

• We'll use the term *global constant* when a global variable's value is not changed after the initial assignment.

• You may use the value of any global constant inside any function you write, as you did in your Racket programs.

```python
tax_rate = 0.13
def total_owed(amount):
    return amount * (1+tax_rate)
```
Errors with global variables

• Consider the following program:
  grade = 87
  def increase_grade(inc):
      grade = grade + inc
  >>> increase_grade(5)
  >>>>

• This causes an error. Why?

• **Do not use** *global variables* in CS116, only *global constants*. 
Changing values of parameters?

Consider the program:

```python
def add1(n):
    n = n + 1
    return n
```

```python
starter = 0
>>> y = add1(starter)
```

- The value of `n` is changed locally, but the value of `starter` is not changed. The change to `n` is a *local* change only.
- Even if `starter` was called `n`, the same behaviour would be observed.
- Note: Things are more complicated with lists. *(Later...)*
Making decisions in Python

As in Racket, in Python we

– Have a Boolean type (Bool)
– Can compare two values
– Can combine comparisons using **and, or, not**
– Have a conditional statement for choosing different actions depending on values of data
Comparisons in Python

- Built-in type `Bool`:
  - `True`, `False`
- Equality testing: `==`
  - Use for most values
  - **Never** use `==` to compare floating point values due to representation and round-off errors
- Inequality testing: `<=, <, >=`
- `!=` is shorthand for not equal
Simplify the following comparisons (assume `math` has been imported)

- $23 < 35$
- $(4 + 3 + \text{abs}(-4)) == 12$
- $5*5 > (3*3 + 4*4)$
- $5*5 \geq (3*3 + 4*4)$
- "abc" != "ABC"
- "elephant" >= "cat"
- $\text{abs}(\text{math.sqrt}(2)-1.41421) \leq 0.001$
Combining Boolean expressions

• Very similar to Racket
  – v1 and v2
  True only if both v1, v2 are True
  – v1 or v2
  False only if both v1, v2 are False
  – not v
  True if v is False, otherwise False

• What’s the value of
  (2<=4) and ((4>5) or (5<4) or not(3==2))

• Python allows short cuts for some expressions:
  x1 < x2 < x3
Evaluating Boolean expressions

• Like Racket, Python uses Short-Circuit evaluation
  – Evaluate from left to right, using precedence
    not, and, or
  – Stop evaluating as soon as answer is known
    • or: stop when one argument evaluates to True
    • and: stop when one argument evaluates to False
  – Note: an expression’s syntax is checked before the expression is evaluated. If there is a syntax error, the expression is not evaluated.

• 1<0 and (1/0)>1
• 1>0 or kjlkjjaq
• True or &32-__-!
Basic Conditional Statement

if test:
    true_action_1
    ...
    true_action_K

def double_positive(x):
    result = x
    if x > 0:
        result = 2*x
    return result
Another Conditional Statement

```python
if test:
    true_action_1
    ...
    true_action_Kt
else:
    false_action_1
    ...
    false_action_Kf
```

```python
def ticket_cost(age):
    if age < 18:
        cost = 5.50
    else:
        cost = 9.25
    return cost
```
"Chained" Conditional Statement

```python
def ticket_cost(age):
    if age < 3:
        cost = 0.0
    elif age < 18:
        cost = 5.50
    elif age < 65:
        cost = 9.25
    else:
        cost = 8.00
    return cost
```
Why are these different?

```
x = 20
if x>10:
    x = x+1
elif x>5:
    x = x-1
else:
    x = 2*x
```

```
x = 20
if x>10:
    x = x+1
if x>5:
    x = x-1
else:
    x = 2*x
```
Conditional statements can be nested

def categorize_x(x):
    if x < 10:
        if x>5:
            return "small"
        else:
            return "very small"
    else:
        return "big"
Python so far

• Our Python coverage is now comparable to the material from the first half of CS115 (without structures and lists)
• Much more to come, but we can now write recursive functions on numbers
“Countdown” Template in Python

def countdown_template(n):
    if n==0:
        return base_answer
    else:
        answer = ... n ...
        ... countdown_template(n-1) ...
        return answer
Revisiting `factorial`

def factorial (n):
    '''produces the product
    of all the integers from 1 to n
    factorial: Nat -> Nat
    example:
    factorial(5) => 120
    factorial(0) => 1
    '''
    if n == 0:
        return 1  # Important to include return statement in both base and recursive cases!
    else:
        return n * factorial(n - 1)
Some limitations to recursion

```python
factorial(1500) ⇒
RuntimeError: maximum recursion depth exceeded
```

- There is a limit to how much recursion Python “can remember”
- Recursion isn’t as common in Python as in Racket
- Still fine for small problem sizes
- We’ll see a new approach for bigger problems.
Examples

Use recursion to write Python functions:

• **sum_powers** that consumes a positive Natural number \( b \) and a Natural number \( n \) and returns the sum

\[
1 + b + b^2 + b^3 + \ldots + b^{n-1} + b^n.
\]

• **is_prime** that consumes a Natural number \( n \) and returns True if \( n \) is prime (its only positive divisors are 1 and \( n \)), and False otherwise.
Background: Alternate representations of boolean values

• In Python,
  – `False` and 0 are equal
  – `True` and 1 are equal
  – Any nonzero number is treated as a `True` expression in an `if` statement

• For clarity, we will continue to use `True` and `False` exclusively for our Bool values (you should follow this practice on assignments)
We are now Python programmers

• Our functions can do more ...
  – May include
    • assignment statements
    • conditional statements
    • function calls (including recursive calls)
    • return statements
  – Changing values of variables is common
  – Order of statements critical
Goals of Module 2

• Become comfortable in Python
  – Changing values of variables
  – Local vs global variables/constants
  – Different formats of conditional statements
  – Recursive functions
